Map of *Certified Speed-Limit Diagnostics for Deployed Superconducting Quantum Processors*

Quantum speed limits · superconducting-qubit gate calibration

54 results · **8** entirely in Lean · **11** partly in Lean · **2** in babelic · **36** checked by a program · written proof only (a result can carry several tags)

Dependencies in the written proof: an arrow A → B means that this *proof* of B uses A. Every result rests on its written proof; the tags record what was checked besides, and each statement's "Evidence & scope" block says how far. The colour of a box is its strongest tag, in the order above; the tags in the box give the rest. Boxes with a thick border are the main results; click a box to read the statement.

Introduction

Remark Abstract (1.1) *n/a*
the abstract (1.1) > at full amplitude, < 2× at the drive HM axes, gates > 10× faster than the decoherence limit; the device's full amplitude, 4.22× for two qubits, a CZ between 0.295 and 0.331 of the qubit-only time (version 3)

Remark §I (1.2) *n/a*
what the paper claims: a speed limit (version 6)fth in version 2), and no new physics

Certified Bounds

Remark Table I (2.1) *n/a*
Table I: the certified statements used in the paper (Lean 4, commit 42f3d9b, Mathlib revision 7f1e binomial)

Remark §XI conflict of interest and the use of AI assistants

What the paper contributes

Two kinds of results, kept apart on this map. **Certified inequalities** (green, linked to Lean): the Margolus–Levitin bound, an L^1 form of Mandelstam–Tamm, the Zieliński–Zych family for every exponent $\alpha>0$, time-dependent two-level bounds, and an entangling-time bound $J\,T\ge\arccos\lambda$ in arbitrary local dimension (a Bell state needs $J\,T\ge\pi/4$, attained; robust versions with state infidelity ε). **Diagnostics on deployed hardware** (grey, with the program that computes each number): how far the calibrated gates of IBM superconducting processors are from those bounds, from public, version-pinned calibration snapshots.

- Single-qubit X gates last a median 11.30 times their two-level speed limit $\pi/\Omega_{\max}$ (1646 qubits, 41 backends), a ratio frozen near 11 from 2021 to 2025.
- Two-qubit ECR/CX gates last a median 4.22 times the known CNOT-class bound $\pi/(2j_q)$; the ratio grew from 2.78 (2021) to 4.26 (2025) because gates got longer, not because couplings got weaker.
- Calibrated drives sit at fixed fractions of an energy splitting: $\Omega_{\rm peak}\approx0.09|\delta|$ (one qubit), $\Omega_{\rm CR}\approx0.45\Delta$ (two).
- The drive-strength convention is fixed by IBM's calibrated π pulses; the $\approx15\%$ residual is explained by the pulse normalization: $\texttt{omegad}\cdot|\mathrm{amp}|\cdot A_{\rm rec}=\pi$ on all 777 qubits to $1.2\cdot10^{-7}$, and the residual tends to $1/(1-e^{-2})=1.15652$.
- At the drive IBM actually uses the X gate is within about 2 of the square-pulse limit (shape factor 1.87, or 2.16 with Qiskit's peak normalization); the 11.3 is against full drive amplitude, which IBM does not use.
- Optimal control on IBM's own transmon model finds feasible X gates of ≈16 ns at IBM's amplitude cap and 4.8 ns at its full amplitude (minimum at least 4.3 ns): 7.4–8.3 times faster than the archived 35.6 ns within the same amplitude budget; ≈3.4 ns needs three times that amplitude (numerical witnesses, not physical floors; the 6-level pulse is converged to 12 levels). The fit $\max(\pi/\Omega_{\max},\,\sim1.1\cdot2\pi/|\delta|)$ is empirical, not a theorem; $T\ge\pi/\Omega_{\max}$ (and $2\arcsin(1-e)/\Omega_{\max}$ in the trace metric) holds for any number of levels.
- With the second transmon level the minimal CZ time lies between 0.295 and 0.331 of the qubit-only time: $0.4632/J\le T_*\le0.5200/J$ (version~3: a two-copy bound and a certified protocol; before, $0.4511/J\le T_*\le\pi/(6J)$; the certified norm bound is $\pi/(8J)$); optimal control reaches error $2\cdot10^{-8}$ at $0.55/J$ (0.35), and for the same task $0.4510/J\le T_*(2\cdot10^{-8})\le0.55/J$. In larger local dimension the construction and the entangling-time theorem approach each other (ratio $\to1$, certified in Lean).

The paper claims no new physics: the speed limits are classical, the two-qubit constants are known for qubits, and the transmon model is IBM's. The entangling-time bound is, for qubits, a known corollary of Dür *et al.* and Vidal–Hammerer–Cirac, new only as a machine-checked, any-dimension assembly. This blueprint is built from a **draft**: the paper's own open items are shown where they matter.

🚀 **Start here:** **Observation §IV-A**: X gates last a median 11.30 times their two-level speed limit at full drive amplitude.

Main results:

- **Theorem §II-A**: Zieliński–Zych: $\pi^{\wedge}\alpha \leq 2M_\alpha \tau^{\wedge}\alpha$ for every $\alpha > 0$
- **Theorem §II-B**: entangling time in any local dimension: $\arccos \lambda \leq J \cdot \Sigma\tau_k$
- **Corollary §II-B**: a Bell vector needs $J \cdot \Sigma\tau_k \geq \pi/4$, in any local dimension $d \geq 2$
- **Observation §III-C**: the drive convention is $c = 1$: IBM's calibrated π pulse rotates by $1.148\,\pi$ with $c = 1$ ($2.296\,\pi$ with $c = 2$)
- **Observation §IV-A**: X gates last a median 11.30 times their two-level speed limit at full drive amplitude
- **Observation §V-B**: ECR/CX gates last a median 4.22 times the CNOT-class bound $\pi/(2jq)$
- **Observation §VI**: single-qubit ratio frozen near 11 from 2021 to 2025; two-qubit ratio 2.78 → 4.26
- **Observation §VII-A**: optimal control: shortest X time found $\approx \max(\pi/\Omega_{max}, 1.1 \cdot 2\pi/|\delta|)$, a speed-limit branch and a leakage-dominated branch
- **Observation §VII-B**: CZ with the second transmon level: error $2 \cdot 10^{-8}$ at $T = 0.55/J$ with local controls $\leq 10J$, i.e. 0.35 of the qubit-only time and 5 % above the construction $\pi/(6J)$

🧭 Fields: where the paper lives and what it connects

Tools taken from other branches

- **Quantum speed limits** → Margolus–Levitin, Mandelstam–Tamm and the Zieliński–Zych family, applied to the drive amplitude of a transmon and to the coupling of a pair — Theorem §II-A, Theorem §II-A, Theorem §II-A, Theorem §II-A
- **Entangling capabilities of Hamiltonians** → minimal interaction time under unbounded local control; Schmidt coefficients and the Fubini–Study angle (Dür et al., Vidal–Hammerer–Cirac, Rudnicki) — Theorem §II-B, Corollary §II-B, Proposition §II-B, Corollary §II-B
- **Formal verification** → Lean 4 + Mathlib: the inequalities of Table I — Theorem §II-A, Theorem §II-A, Theorem §II-A, Theorem §II-B, Corollary §II-B, Proposition §II-B, Theorem §II-B
- **Optimal control** → piecewise-constant GRAPE control on a 4-level transmon with a bound on the drive — §VII-A, §VII-A, §VII-A, §VII-A, §VII-B

What the results serve

- **Gate design on superconducting processors** ← how far calibrated gates are from the physical limit, and which fractions of the energy splittings the calibrations use — §IV-A, §V-B, §IV-C, §V-D
- **Reproducible hardware benchmarking** ← version-pinned public calibration snapshots as a citable source, and a stratified control against confounding by epoch — §VI, §VI
